            The Case of Antigua-Barbuda-Redonda
INTRODUCTION

This base of this report was initially prepared in 1998 by Island Resources Foundation to assist a potential donor in evaluating the global significance of the biodiversity of the Eastern Caribbean, specifically the eight GEF-eligible states: Antigua-Barbuda, Barbados, Dominica, Grenada, St. Kitts-Nevis, St. Lucia, St. Vincent and the Grenadines, and Trinidad-Tobago. The report’s primary focus was to collate and interpret data on the terrestrial and marine biodiversity of the region.

In the ensuing year, Island Resources Foundation had an opportunity to carry out a more comprehensive biodiversity assessment of the country of St. Kitts and Nevis, as the Foundation had earlier undertaken for Antigua and Barbuda, providing a level of detail for these countries that does not yet exist for other Eastern Caribbean states included in this report. It is our hope that this document can serve as a working tool for biodiversity conservation efforts in the region and that it will be continually refined and updated as additional data become available.

Most modern conservation assessments employ a three-part framework: biological status; threat; and response. This report predominantly focuses on the region's biological status. It is not a conservation assessment, although on occasion, we offer brief comment on conservation status. To produce a proper conservation assessment would require additional information about biodiversity threat and response factors. However, even without elaborating on the specifics, it is worth noting the concern within the international community that the small size, insularity, and economic dependence of the Eastern Caribbean states make them especially vulnerable to exploitation of their natural resources, including their biodiversity.

TERRESTRIAL BIODIVERSITY: ECOSYSTEMS

We began our analysis of terrestrial ecosystems of the Eastern Caribbean by reviewing A Conservation Assessment of the Terrestrial Ecoregions of Latin America and the Caribbean Status (WWF/WB, 1995). This document represents the most comprehensive attempt to date to identify for the Americas the terrestrial geographic priorities for biodiversity conservation based on the integration of biological distinctiveness and conservation status. Our analysis explores the implications and suitability of this report and concludes that its scale is too large to be effective in assessing the biodiversity of the Eastern Caribbean. We conclude this section by suggesting alternative, scale-appropriate classifications and approaches.
**WWF/WB Conservation Assessment of the Terrestrial Ecoregions of Latin America and the Caribbean**

The WWF/WB study identifies 11 *Major Habitat Types*, which are divided into 178 terrestrial non-mangrove and 13 terrestrial mangrove *ecoregions*. Within this exercise, an ecoregion is intended to be the fundamental unit of conservation planning, “the minimum level of resolution required for achieving regional representation and effective conservation planning... [It] should identify an area over which a single conservation strategy could be effectively applied” (p. 4). The report provides profiles of each ecoregion, identifying its ‘final conservation status’ and ‘biological distinctiveness’, which are integrated to determine its ‘biodiversity conservation priority’.

Of the 11 Major Habitat Types identified for the Americas, seven occur in the Caribbean; only four of these are identified within the Lesser Antilles. The four Major Habitat Types contain seven ecoregions in the Lesser Antilles:

¹ For the most part, the exercise treats ecoregions simply as “geographically discrete units of Major Habitat Types”. However, the fuller definition of ecoregions refers to “geographically distinct assemblages of natural communities that share a large majority of their species, ecological dynamics, and similar environmental conditions, and whose ecological interactions are critical for their long-term persistence” (p. 14); and “on the basis of this definition, some ecoregions... contain a mosaic of distinct habitat types” (e.g., the Cerrado of Brazil is an ecoregion listed under the “Grasslands/Savanna/Shrublands” Major Habitat Type, even though it also contains areas of other Major Habitat Types).

² Mangroves: The WWF/WB report states that its evaluation of mangroves is less comprehensive than its evaluation of other terrestrial systems, and much of its discussion is limited to the “non-mangrove ecoregions”. However, it does identify 13 major bio-

Note: The roman numerals indicate biodiversity conservation priority classes:

Level I = Highest Priority at Regional Scale (shaded area)
Level II = High Priority at Regional Scale
Level III = Moderate Priority at Regional Scale
Level IV = Important at National Scale

The application of the matrix in Table 1 to the seven ecoregions within the Eastern Caribbean results in the ecoregion profiles shown below (WWF/WB, 1995):

**Windward Islands moist forest-Windward Islands**: Vulnerable; Bioregionally Outstanding; Moderate Priority at Regional Scale.

The moist forests of both the Windward and Leeward Islands are comprised of many disjunct forests on different islands. Because many species are endemic to forests on a single island, conservation strategies should emphasize adequate representation of each island. Urban development pressures, pollution, grazing, roadbuilding, and exotic invasions threaten the ecoregion. The types and intensity of threats vary among different islands.

geographic "complexes" (used more or less interchangeably with "ecoregions"). Subsequent to the publication of this report, WWF convened a workshop of the leading mangrove specialists of the Western Hemisphere to try to apply the methodology of the first assessment to prioritize mangrove conservation issues. They identified the mangroves of the Lesser Antilles, from among all of those of Latin America and the Caribbean, as being the most impacted by development and the ones at the greatest conservation risk (WWF, 1996).
Leeward Islands moist forest-Leeward Islands: Relatively Stable; Bioregionally Outstanding; Moderate Priority at Regional Scale.

Biodiversity considerations are discussed under Windward Islands moist forests. Urban development pressures, pollution, grazing, road-building, and exotic invasions threaten the ecoregion. The types and intensity of threats vary among different islands.

Windward Islands dry forest-Windward Islands: Endangered; Locally Important; Moderate Priority at Regional Scale.

Agricultural expansion, grazing, firewood gathering, and development are threats to the ecoregion.

Leeward Islands dry forest-Leeward Islands: Critical; Locally Important; Moderate Priority at Regional Scale.

The ecoregion faces threats from clearing for development, seasonal burning, firewood gathering, and heavy recreational use.

Windward Islands xeric scrub-Windward Islands: Endangered; Locally Important; Moderate Priority at Regional Scale.

Grazing, woodcutting, and the conversion and resource exploitation associated with increased urbanization pose threats to the ecoregion for the foreseeable future.

Leeward Islands xeric scrub-Leeward Islands: Critical; Locally Important; Moderate Priority at Regional Scale.

Grazing, woodcutting, and the conversion and resource exploitation associated with increased urbanization pose threats to the ecoregion for the foreseeable future.

Lesser Antilles mangroves-Lesser Antilles: The mangroves were not ranked in a manner comparable to the non-mangrove terrestrial ecoregions, but see footnote 2.

We believe that the WWF/WB report fails in several important respects when applied to the Eastern Caribbean:

- The scale adjustments are still too coarse for assessing the Eastern Caribbean.
- The seven ecoregions listed do not adequately portray the biodiversity within this region in a manner that allows them to be useful as conservation tools.
- It is not an adequate portrayal of the Eastern Caribbean’s contribution to global biodiversity.

**Scale Issues**

The WWF/WB study divided all of Latin America and the Caribbean into nine bioregions—Northern Mexico, Central America, Northern Andes, Central Andes, Southern South America, Eastern South America, Amazonia, Orinoco and Caribbean. Seven of the eight countries targeted in the IRF assessment of Eastern Caribbean biodiversity are located in the Caribbean bioregion; while the eighth country—Trinidad and Tobago—is in the Orinoco bioregion.

The WWF/WB assessment tries to ensure that there is bioregional representation, and the discussion in the report of this topic is especially valuable when considering the application of the integration matrix to the Eastern Caribbean.

*The matrix ... provides, by Major Habitat Type, a set of Highest Priority at Regional Scale ecoregions (level I) for all of Latin America and the Caribbean. However, this list within each Major Habitat Type does not necessarily ensure bioregional representation.*

Bioregional representation is important because of the dissimilarities in the species and natural communities of ecoregions within the same Major Habitat Type but from different biogeographic zones of Latin America and the Caribbean; geographic replacement of species occurs as range boundaries, environmental gradients, and physical barriers are crossed at large geographical scales. By including bioregional representation as a goal in a regional biodiversity strategy, problems of scale are also dealt with in a more objective fashion. For example, many Caribbean ecoregions that share the same Major Habitat Type with continental ecoregions come out poorly in priority rankings. Typically, small island faunas and floras are depauperate compared to continental biotas because of size and isolation. Ideally however, at least one example of each Major Habitat Type in the Caribbean should be considered as Highest Priority at Regional Scale to reflect the importance, at the Latin America and the Caribbean scale, of the biodiversity of that bioregion.

We propose that within each bioregion each constituent Major Habitat Type be represented—subject to certain conditions—by at least one ecoregion classed as Highest Priority at Regional Scale. We attain this goal by “upgrading”, when necessary, a single level II or level III ecoregion (but never a level IV) to “level I.” We choose a level II over a level III ecoregion and a worse conservation status over a better conservation status. Only level III ecoregions that are Critical, Endangered, or Vulnerable are considered eligible. If there is a tie between two or more ecoregions, we choose the ecoregion with the highest biological distinctiveness … (WWF/WB, 1995, p. 11).

Despite this attempt to ensure geographic representation, the approach used by WWF/WB fails in regard to the Eastern Caribbean. It simply does not go far enough to be useful in assessing landscape biodiversity of, or within, the Eastern Caribbean. The nine bioregions used in the report may be a manageable number for dealing with an area greater than a continent, but it is so coarse that the Eastern Caribbean becomes lost. The result is one ‘upgrade’: the Leeward Islands xeric scrub is moved from level II to level I. We feel strongly that this is not the only habitat within the Eastern Caribbean warranting the attention of the global conservation community. Furthermore, the fact
that the Eastern Caribbean includes two bioregions—Trinidad and Tobago, which is classified within the Orinoco bioregion, as well as the Lesser Antilles, which is classified within the Caribbean bioregion—complicates the application of the WWF/WB exercise to an assessment of the biodiversity significance of the Eastern Caribbean.

The WWF/WB report does include a discussion of the “Application of the Methodology to Finer Geographic Scales”, recognizing that “regional priority-setting exercises—by virtue of their coarse scale—can seldom identify where the most important investments should be made within ecoregions nor what to do at those sites to best conserve biodiversity” (pp. 46-47). The discussion raises important points and offers excellent suggestions at the intra-ecoregional level. We note, however, that this discussion does not contribute to addressing the concern that we raise above, namely, that ecoregions, as defined in WWF/WB's report, are not the appropriate units to use in evaluating biodiversity conservation of the Eastern Caribbean.

A secondary concern in the application of these ecoregions to the eight GEF-eligible countries in the Eastern Caribbean has to do with the great variability among these islands. Table 2 illustrates the conservation status and biodiversity condition for nine ecoregions for the eight GEF-eligible countries in the Eastern Caribbean. For terrestrial ecoregions, these assessments of biological significance reflect some of the actual discussions which resulted in the World Bank/WWF hemispheric assessments. For the Mangrove and two illustrative marine habitats, the IUCN standards for conservation status and the World Bank/WWF criteria for biological distinctiveness were applied by experts who had participated in the terrestrial ordering exercise in Miami in October of 1995. To simplify the biological distinctiveness ratings for this illustration, the ratings are “outstanding, important, and significant,” based on a regional estimate of relative numbers of endemic or threatened migratory species which would be affected by changes in the major habitats characterizing each ecoregion.

These status estimates are provided to illustrate the wide variety of conditions encountered in the eight GEF-eligible countries in the Eastern Caribbean. They are not intended to define those conditions, although such an assessment would be a desirable product of a potential GEF biodiversity project for these eight countries, and one which might lead to regional cooperation and coordination of biodiversity conservation at an operational level which has been heretofore unattainable.

**Finer-scale Classifications of Terrestrial Ecosystems of the Eastern Caribbean**

Unlike the analysis of biodiversity at the species level—where a consensus exists on definitions—analysis of biodiversity at the landscape level is greatly affected by the criteria used to define the landscape unit and by the scale on which the assessment is applied. Not just the definitions, but “the relationships between ecological patterns and processes change with the scale of observation” (Biodiversity Support Group, 1995; Jones, et al., 1998).
The most influential work on classifying the vegetation of the Caribbean remains that of Beard (1949; 1955). He recognized 28 categories within 6 major forest types (some of the categories did not apply to the Lesser Antilles, and in some cases there may no longer be viable samples). Most of the researchers that followed based their approach to vegetation classification on Beard’s work. Howard (1974), the editor of the definitive flora of the region, used ecological factors to modify Beard’s vegetation classification, and he identified 14 categories within 3 major groupings (Table 3).³

³ Another valuable contribution to the understanding of the flora of the Caribbean is the Centres of Plant Diversity project. Although the data in Centres of Plant Diversity: A Guide and Strategy for Their Conservation (Davis, et al., 1997)³ are not presented in a format that is directly applicable to an assessment of the biodiversity of the Eastern Caribbean, this project and its collaborators represent an important resource for any conservation effort in the region.

Our experience from Antigua-Barbuda and St. Kitts-Nevis, where we have recently completed an intensive and relatively comprehensive biological inventory, offers an additional perspective. The system that we used was based on the National Vegetation Classification System being prepared by the U.S. Federal Geographic Data Committee (FGDC, 1996); and, in particular, we referenced the Vegetation of the West Indies, an application of this system to the Caribbean by the Southeast Regional Office of The Nature Conservancy (Weakley, 1996). The U.S. national effort is part of a global initiative to characterize land cover and land use in a standardized manner.

In Antigua-Barbuda, we identified 54 Alliances and Associations—the basic units of conservation planning within this system—within the country of Antigua-Barbuda. Each of these was sufficiently different from one another to be distinguishable in the field. We then identified the conservation status of each of the 54 Alliance/Associations, using a two-tier labeling system modified from the Red Data Book Categories of the International Union for Conservation of Nature and Natural Resources: 16 Alliances/Associations were classified as Rare (very restricted in distribution and/or size); and 5 of these were also considered Endangered (in danger of extirpation).

In St. Kitts-Nevis, the flora could be differentiated into 36 vegetation communities. Eleven are Common, 9 are considered Rare and 16 are Uncommon. The Common communities, with the exception of one coastal community, can be considered Stable, and, fortunately, many of the Rare and Uncommon communities can also be considered Stable because of their isolation and difficult access. However, nearly half (16 of 36) of the vegetation communities are at risk; three of these are Endangered.

An obvious conservation priority for each of these countries is ensuring that at least a few sites of each of these natural communities are protected. Not only would this pro-
tect the country's biodiversity at the ecosystem level, but at the species level it should provide substantial protection of much of the flora and fauna.

Thus, we have at least three different levels at which to consider the issue of ecosystem biodiversity in the Eastern Caribbean. Clearly, the WWF/WB exercise, whose objective was to identify geographic biodiversity conservation concerns for all of the Americas, could not be expected to operate at the fine level of detail that we used in Antigua-Barbuda and St. Kitts-Nevis. Equally clear, the finer-scale level represents a valuable tool in efforts to ensure that each country protects its ecosystem biodiversity. Furthermore, it seems reasonable that something on the order of the 14 ecological categories identified by Howard—rather than just the 4 used in the WWF/WB report for all of the Lesser Antilles—could serve as an appropriate compromise for a careful consideration of landscape-level biodiversity of the Eastern Caribbean.

Unfortunately, while Howard used ecological categories in the descriptions of plant species, the Flora does not provide any text or maps showing the distribution of these vegetation types in the Eastern Caribbean. Such an analysis should be a priority in any effort to protect regional biodiversity.

**TERRESTRIAL BIODIVERSITY: SPECIES RICHNESS AND ENDEMISM**

The number of species that occur in the West Indies is influenced by its small size and insularity, factors that contribute to the relatively high endemism and vulnerability of its biota.

In Appendix 1, we summarize much of the available data on the number of plant and animal species found on each island, with notes on endemism. The data on mammals, reptiles, birds and plants are fairly complete, although it is important to note that, in general, these islands have not been adequately scientifically investigated. We are not suggesting that they contain large numbers of species new to science, but rather that the information on presence/absence of species and their distribution is very incomplete.

Data on other taxa are much less comprehensive and reliable. For example, the freshwater fish fauna of the Antilles is believed to consist of 71 "mostly endemic" species, primarily in Cuba and Hispaniola (Lee et al., 1983). According to this source, only one of these (Rivulus cryptocallus, from Martinique) is endemic to the Lesser Antilles, but we were not able to find accounts of any comprehensive surveys of the islands of the Lesser Antilles (Burgess and Franz, 1989).

The state of knowledge of the invertebrate fauna is even more limited. We include a more detailed discussion of invertebrate biodiversity below, because we feel that it of-

---

*Some of the category labels may misleadingly suggest abiotic communities, but each refers to a distinct biological community of plants and associated animals.*
fers a biodiversity perspective not possible from analyses of the more traditional foci such as mammals and birds.

**Invertebrates**

One of the few invertebrate groups that has received substantial attention in the Caribbean is the Coleoptera. The notes below, paraphrased from discussions with Dr. Michael Ivie, an entomologist who has worked extensively in the Virgin Islands, offer an interesting and valuable perspective:

*Beetles (Order Coleoptera) are the single largest group of organisms on earth. For the West Indies, it is even more dominant than elsewhere because so many other groups are relatively underrepresented or already extinct. Beetles occupy the largest number of trophic levels, have the largest size range, and the greatest ecological diversity of any group of West Indian organisms. Yet, we know very little about them. Further, our knowledge is very uneven geographically, with the best data existing for the Virgin Islands and Guadeloupe.*

Based on data from the better-studied islands [Table 4], we know that the area and elevation of an island seem to be the best predictors of its species diversity. Thus, St. Kitts, which is larger and higher than St. Thomas should have more beetle species, yet less than 10% of the number known for St. Thomas have been recorded for St. Kitts. Redonda, with 1 known species, would be expected to have more species than Guana, BVI, which has 250 catalogued species.

*In the Virgin Islands, we have identified some 1400 species; 50% or more of the species on each island are endemic to that island, or at least to that island bank (the land mass that would have been exposed above sea level during the low-water maximum of the Pleistocene period; i.e., ~200m contour). The Northern Leewards area (from Sombrero, Anguilla to Montserrat) probably contains well over 1,000 undescribed, undiscovered species (and many genera) of beetles alone on the 8 separate Pleistocene banks.*

Ivie goes on to argue that a critical step in trying to identify biodiversity conservation priorities requires that we have a relatively good inventory of at least some groups; and that the best candidates are the vascular plants and at least one of the insect orders. Given the well-established evolutionary and ecological relationship between plants and insects, the inventories would target as many different plant communities as could be identified. Our most effective measure to safeguard the biodiversity of plant species and terrestrial invertebrate biodiversity would be to protect, to the fullest extent possible, representatives of all the different vegetation communities that occur in the Eastern Caribbean.

**Birds**

The islands of the Lesser Antilles have a particularly distinct avifauna, including seven endemic genera—*Catharopeza, Cichltherminia, Cinclocerthia, Cyanophaià, Leucopeza,*

---

5 There is an ongoing effort to identify similarities and reconcile differences if they exist between Partners in Flight and Birdlife International regarding regional avian conservation concerns. Both these initiatives treat Trinidad and Tobago separately from the rest of the Eastern Caribbean, as does IRF in this report. Contacts for these organizations:

David Wege; Americas Programme Manager; Birdlife International; Wellbrook Court; Girton Road; Cambridge, CB3 0NA, UK; e-mail: <david.wege@birdlife.org.uk>.

Melanospiza and Ramphocinclus (Birdlife International, 1998). Collectively, they support 25 endemic bird species and an additional 11 subspecies, some of which are expected to be elevated to species status; at least 23 of these taxa are likely vulnerable or known to be highly endangered (C. Hunter, U.S. Fish and Wildlife Service, pers. comm.). Using slightly different criteria, Birdlife International has prepared an account of ‘restricted-range species’. Restricted-range species are inherently vulnerable by virtue of their limited distribution, regardless of other factors—they account for 75% of all threatened bird species. Birdlife International identifies 2,600 restricted-range species globally, 130 of which are in the Caribbean; 24 of these are in the Lesser Antilles Endemic Bird Area. Details on endemism—single-island, multi-island, and regional—are provided for each country in Appendix 1.

The Eastern Caribbean is known to serve as an important link in the seasonal migrations of numerous birds. For at least one species, Blackpoll Warbler, most of its total world population is believed to use this area for stop-over sites during autumn. Several species of thrushes, vireos, cuckoos and warblers also migrate through the Eastern Caribbean in large numbers at this time of year. This period overlaps the late summer-autumn tropical storm season, and migrants forced to land are completely dependent upon habitat provided by these Lesser Antillean islands. Some of these species, including Bicknell’s Thrush, which is considered a high priority migrant by the U.S. Fish and Wildlife Service, may overwinter in the Lesser Antilles—often in the same habitats supporting highly vulnerable endemic species. The Eastern Caribbean also provides critical stop-over sites for numerous shorebirds that migrate along the Trans-Atlantic route to South America after breeding further north in the temperate zone (C. Hunter, U.S. Fish and Wildlife Service, pers. comm.).

The numerous islands of the West Indies, some little more than rocky outcrops, contain globally significant breeding sites for approximately 25 species of seabirds, many of which are endemic species, sub-species or races. The most recent annual meeting of the Society for Caribbean Ornithology convened a workshop on this topic, and will soon release a report identifying all the known sites, with estimates of the numbers of individuals they support. The preliminary findings highlight: 7 ‘high priority’ species with 4,000 or fewer breeding pairs; 6 ‘priority’ species with between 4,000-8,000 breeding pairs. In at least two cases, Roseate Tern and Magnificent Frigatebird, these small breeding populations represent a substantial percentage of their global populations. The final report is expected to convey the concern shared by the specialists participating at the workshop, who noted that

1) global populations of most seabirds are on the decline;

2) generally, the populations of nesting seabirds tend to be fairly isolated from one another; so that

3) the deterioration or demise of nesting sites may significantly diminish the genetic pool of any given species (D. Lee, North Carolina State University, pers. comm.; Shreiber, Ornithological Society, pers. comm.).
The islands of the Eastern Caribbean share many of the same bird species, face similar conservation issues and threats. We include a profile of one of the islands, Antigua-Barbuda-Redonda, as Appendix 2, in order to look at these avian issues in greater detail.

**PROTECTING TERRESTRIAL BIODIVERSITY**

To protect the terrestrial biodiversity of the eight GEF-eligible countries of the Eastern Caribbean, biodiversity conservation efforts must operate at the island-specific ecosystem level. Certainly, there are selected narrower targets—endemic and endangered species, for example—that warrant conservation attention, but the most effective protection that will provide coverage for the greatest number of species will require an ecosystem approach.

This is especially relevant for the islands of the Eastern Caribbean, which have:

- a large number of geographically small ecoregions;
- a relatively small number of locally and regionally threatened and endangered, unique or regionally endemic species, especially sparse in relation to the number of potential habitats or ecosystems; and
- extremely high costs of land (average costs of over US$10,000 per acre for undeveloped land are common), implying politically sensitive decision-making in the selection and management of protected areas.

As has been noted elsewhere in this report, neither the ecosystems or the vegetative systems of the islands of the Eastern Caribbean have yet been classified in a manner that could guide development of a parks and protected areas (PPA) system whose objective is the protection of terrestrial biodiversity. Development of appropriate classification systems is certainly feasible, and it is strongly recommended that these efforts be given the highest priority, within a general program to improve management of biodiversity resources.

The existing protected areas identified in Appendix 1 provide a valuable foundation for future efforts. Some include critical habitat needed to preserve the fauna and flora of the region's islands. But, it must be noted that biodiversity conservation per se was rarely, if ever, the major criterion in the selection of these sites. In conjunction with implementation of the classification systems proposed above, it should be possible to review the existing PPAs in the eight GEF-eligible islands of the Eastern Caribbean and identify gaps that need to be filled to ensure long-term protection of biological diversity.
Because a detailed vegetation classification and a biodiversity profile have been prepared for Antigua-Barbuda, it is possible to preliminarily identify significant sites for biodiversity conservation in that country. These should include the following:

- The northeastern coastal wetlands of Antigua, adjoining nearshore marine habitats and the adjacent offshore islands
- Codrington Lagoon on the island of Barbuda
- The high elevation areas of Antigua, including and between Wallings and Boggy Peak
- The remaining dry forests of Antigua and Barbuda
- The island of Redonda.

These sites are large relative to the size of the country, and we are not suggesting that they be "fenced off". Instead, we consider them good candidates for protection, using a variety of techniques that feature multiple-purpose sustainable usage of an area while protecting its core biological resources.

MARINE BIODIVERSITY

We believe that the marine biodiversity of the Eastern Caribbean is a valuable global resource whose conservation warrants the concern and assistance of the international community. Virtually all aspects of marine biodiversity are much more poorly understood than for terrestrial biodiversity (de Fontaubert et al., 1996), including the central issue of conservation priorities. We know that while the marine environment is home to only 250,000 of the 1.7 million species catalogued to date, it has been much less explored. Although there probably are fewer species in the marine environment than on land, marine animals show more diversity at the evolutionary and taxonomic level. Of the 33 animal phyla (i.e., the major branches on the tree of life), all but one have some species members in the sea (in contrast, only about half of the phyla have any representative species on the land; de Fontaubert, 1996; WR Report, 1996).

The most recent publication of the annual stock-taking of natural resources, World Resources: A Guide to the Global Environment, has this to say about marine biodiversity:

> Because only about 7% of the oceans have been sampled, the current state of knowledge regarding species distribution and hot spots is poor...Patterns of marine endemism are generally not well known. Most marine species appear to have much larger ranges than terrestrial species because of their life cycles. Many species, including sedimentary organisms such as mussels and coral, produce free-floating planktonic larvae. Their young may drift for as little as a few hours or up to 6 months or more—depending on the species—before changing into their adult forms. This free-floating stage permits these species to disperse well beyond spawning areas.

---

<sup>10</sup> Lindsay, K, and B. Horwith, 1997a; and Horwith, B. and K. Lindsay, 1997a.
Beyond simply looking at areas with high levels of species richness and endemism, several other criteria can be applied to define conservation priorities. These include protecting ecosystem diversity (preserving representative samples of all habitats and unique ecosystems) and conserving areas noted for their high levels of biological productivity (because they are rich fishing areas) as well as areas that serve as breeding grounds and nurseries (such as estuaries and mangroves) for marine species. (WR Report, 1996).

**Marine Ecosystem Biodiversity**

The task of protecting marine ecosystem diversity begins with the same challenges as on land—defining ecological criteria that allow one to define marine ‘ecosystems’ and identifying their locations. An ongoing initiative led by The Nature Conservancy (TNC) represents the state-of-the-knowledge on marine ecosystem biodiversity in the Caribbean. TNC identified approximately 10 marine ‘provinces’, analogous to the Major Habitat Types employed in the WWF/WB terrestrial assessment. The Central Caribbean was selected as the pilot area to which TNC applied a finer-scale analysis and identified 51 ‘coastal systems’ based on differences in biota (e.g., coral, sea grass and mangrove) and physical factors (such as water circulation patterns, proximity to land, etc.). These coastal systems represent ecological—not just geographic—differences, so in this respect they are considerably more detailed than the terrestrial assessment. This marine assessment resulted in a two-volume report that is currently under review by a small group of marine specialists that includes the workshop participants that generated the data (J. Tschirky, TNC, pers. comm.).

Coral reefs are considered the mega-diversity areas of the oceans, often compared to tropical rainforests in terms of their biodiversity. They contain an estimated 25% of all marine species and 20% of catalogued marine fish species; yet, they comprise only about 0.1% of the earth’s surface. The tropical Atlantic is believed to contain approximately 15% of global coral coverage, the majority of which (9% of global coral coverage) occurs in the Caribbean (de Fontaubert, 1996; WR Report, 1996).

By some estimates, 10% of the world’s coral reefs has already been destroyed, and another 60% is in danger of being lost within the next 20 to 40 years (de Fontaubert, 1996). These grave projections may be even worse for the Eastern Caribbean, which faces unprecedented development pressures (Island Resources Foundation, 1991).

The World Resources Institute is working on a global assessment of threats to reefs, which should be published in late June, 1998. WRI staff has agreed to share preliminary products of that study with Island Resources Foundation. In spite of the fact that this paper generally does not discuss issues of threat or response to biodiversity loss, we discuss these results here because little information on threats to reefs is otherwise available.

For purposes of its *Reefs at Risk* initiative, World Resources Institute identifies four major threats to reefs:
• Sediment and land-based pollution
• Exploitation
• Marine sources of pollution
• Coastal development.

These data on ‘threat condition’ were translated into a ‘reefs at risk’ assessment, with disturbing findings: the coastal and near shore waters of the eight countries of interest in the Eastern Caribbean all received high or very high risk assessments (WRI):

• Antigua-Barbuda,
• St. Kitts,
• the leeward (west) side of Dominica
• the leeward (west) side of St. Lucia,
• south and west coasts of Barbados,
• St. Vincent and Bequia,
• Grenada and Carriacou, and
• portions of Tobago.

In other words, the World Resources Institute assessment finds virtually all of the reef systems of the eight proposed biodiversity programs to be highly threatened from the direct and indirect effect of human actions (see Appendix 3 for more details on this initiative).

As we did elsewhere in this report in regard to other natural resource topics, we include a profile to allow for a more detailed examination of a selected country. The data on the marine environment of Antigua-Barbuda are the most recent and most relevant for biodiversity considerations among the target countries; and most of the issues that apply to that country pertain more broadly to the Eastern Caribbean (Appendix 4).

Global significance of reef risk in the Eastern Caribbean: The high risk ranking given to the reefs of the Eastern Caribbean has special global significance given that its reefs are upwind and upstream of all other reef systems in the Wider Caribbean. The dynamics of large marine ecosystems in general, and the Caribbean specifically, are not well known. (IOCARIIBE has been coordinating a research proposal on this subject.) In the absence of such knowledge, prudence dictates that the biodiversity of the Eastern Caribbean reefs should be especially cared for because of the reasonable assumption that reefs in the Eastern Caribbean are the sources of both “seed stock” and potential water-born pathogens which might affect all reef systems in the path of the wider Caribbean circulatory systems, including coastal U.S. areas, all of the Bahamas Bank, Bermuda, and the Azores (Ogden, 1997).

Marine Mammals

Within the waters of the Caribbean, 26 of the global total of 78 species of cetaceans have been recorded (Gricks, 1994).

Conservation implications: While there are no country-specific conservation issues regarding cetaceans, many species are endangered throughout their range by hunting and/or over-fishing of their prey. Perhaps the greatest threat, however, is chemical pollution of the world’s oceans. Bio-accumulation of PCBs and other toxins in the animals’ fat reserves are suspected to contribute to breeding difficulties and illnesses associated with pollution-suppressed immune systems.

PROTECTING MARINE BIODIVERSITY

A 1995 initiative by the Great Barrier Reef Marine Park Authority, World Bank and World Conservation Union identified priority areas for the establishment and management of a global representative system of marine parks and protected areas to conserve marine biodiversity and achieve sustainable use of the marine environment (Kelleher, et al., 1995). This report identified priorities primarily on the basis of ecological and biogeographic criteria, but it also included an assessment of the feasibility of establishing and managing the selected sites as marine protected areas. Two sites were identified within the Lesser Antilles:
Barbuda (a part of the two-island country of Antigua and Barbuda). Barbuda is a low-lying limestone-based island with relatively uniform topography (approximately 62 square miles in size). Coral reefs (extensive development on the eastern coast), mangroves and sandy beaches characterize its coastline. A lagoon averaging about one and a half miles wide runs along most of the western side of the island which, along with satellite ponds, provides a variety of feeding habitats for native and migratory species. The island consists of a group of well-conserved biotypes (coral reefs, sandy beaches and lagoons) of particularly high species richness.

Soufriere Marine Management Area (island of St. Lucia). The Soufriere region is located on the southwestern coast of St. Lucia and is important for its reef resources and the quality of its coastal landscapes, as well as the economic activities these resources support. Coral veneers in the vicinity of Soufriere provide spectacular attractions for divers. The area has been established as a marine management area that includes marine reserves, fishing priority areas and multiple-use areas, with a zoning system that seeks to respond to various resource users in order to achieve compatible conservation and development objectives.

Although this global assessment represents a valuable contribution to marine conservation efforts in the Caribbean, that effort will undoubtedly be further enhanced by the ongoing TNC-led initiative referred to previously in this report.

FACTORS COMPLICATING AN ASSESSMENT OF EASTERN CARIBBEAN BIODIVERSITY

The small size and insularity of the land areas of the Eastern Caribbean correspond to lower numbers of terrestrial species within this region relative to larger, continental areas. But the isolation of the islands also leads to higher levels of endemism than for comparably-sized continental areas. The absence of reasonably comprehensive and current biological data, illustrated dramatically for the Coleoptera, is an obstacle affecting the assessment of almost all of the taxa, to varying degrees. For example, in regard to the herpetofauna, a group that is relatively well-studied, there are about as many subspecies and races identified as there are species; and scientists suspect that there are several cases of taxonomic misidentification and that several 'species' now thought to be distributed throughout multiple islands will turn out to be single-island endemics (Johnson, 1988; Schwartz and Henderson, 1991; Woods et al., 1989; Horwith and Lindsay, 1997).

For small islands, a critical question is not how many species occur on a hectare of land, but how many of those species would be lost if that hectare was lost. Whereas most continental species have huge ranges, the species occurring on small islands often do not, and therefore the protection of each hectare is far more critical. The majority of the snake species found in the Lesser Antilles are endangered—two species of snake, one
restricted to a tiny islet off the shore of Antigua and the other restricted to tiny islet off the coast of St. Lucia—are among the world’s rarest animals. A preserve in Antigua would do nothing to safeguard the St. Lucian endemic snake species, which lives only a few hundred km away. Looked at from another perspective, using Coleoptera to illustrate the point, the Virgin Islands supports an endemic species on every 0.6 hectare, while Brazil takes 5.87 hectares to do the same (M. Ivie, University of Montana, pers. comm.).

This report also argues for the need to recognize the importance of the Eastern Caribbean for marine and terrestrial migratory species, while acknowledging the difficulty in quantifying this contribution. Many of these species are not restricted to the region, but they require access to critically threatened habitat—even if this habitat may not otherwise be considered biologically distinctive within a global context. It would be prudent for the international community to act under the assumption that the Eastern Caribbean is serving as a critical link in the continued existence of this large group of migratory species.

Even though there are situations where it is justified to set conservation priorities, the task should be approached cautiously and conservatively:

This should not be a counting game among locations... Comparing a large place with 20 vulnerable endemics with a small place with 5 vulnerable endemics is perhaps not the best way to go in establishing conservation priorities. Instead, should not the point be to emphasize that there are 25 vulnerable species that need attention? (C. Hunter, U.S. Fish and Wildlife Service).

| Note: References to “CEP” in the above table refer to the “Country Environmental Profiles” published in 1991 by Caribbean Conservation Association and Island Resources Foundation. Profiles were prepared for the following target countries: Antigua-Barbuda, Dominica, Grenada, St. Kitts-Nevis, St. Lucia, and St. Vincent and the Grenadines.
Appendix 2

Avian Conservation in the Lesser Antilles:
The Case of Antigua-Barbuda-Redonda

Research during the past decade has substantially increased the number of bird species recorded for Antigua and Barbuda from 106 (Faaborg and Arendt, 1985) to 182 (Gricks et al., 1997). Approximately two-thirds of these species are migratory. Of the other third, some 20 of the species that occur in the country are restricted to the Caribbean basin (primarily West Indian, but some also occurring on adjoining mainland). The country has at least 8 Lesser Antillean endemics, 1 of which, a sub-species or race of the Adelaide's Warbler, is found only in Barbuda and St. Lucia.

Several species are known from the fossil record: 3 of these are extinct; 12 are extirpated from Barbuda and 8 are extirpated from Antigua (Pregill et al., 1994).

Several two-to-three-year periods of severe drought over the past two decades are assumed to have impacted bird populations; as did the hurricanes of 1995. Drastic reductions in the populations of many of the small song bird species were noted, especially for the three hummingbird species. Unregulated and excessive misuse of pesticides also may be affecting bird populations, especially species that frequent farms and residential areas. For example, older people say that there have been reductions in the numbers of Ground Dove and Zeneida Dove, even though hunting of these two species has declined over the past several decades to the point that it is only a minor recreational activity.

Conservation implications: The major threat to local birds is loss of habitat, in particular mangroves and other wetlands. Even mangroves with nesting herons and chicks have been bulldozed. Species that are particularly at risk in Antigua due to deterioration of wetland habitat include: Black-crowned Night Heron, West Indian Whistling Duck, White-cheeked Pintail, Ruddy Duck, Masked Duck, Clapper Rail, Caribbean Coot, and the Magnificent Frigatebird. Despite the conservation importance of mangroves and associated wetlands, and despite the alarming rate at which they are being destroyed and degraded, we do not have accurate, quantitative data on the amount that has been lost in recent years or the amount remaining. Bacon (1991) provides the best information, but it lacks adequate detail at the site level and is in need of updating. The destruction of any particular site is unfortunate, and should only be allowed if justified by a careful cost-benefit analysis; but it is the cumulative impacts of the loss of these sites that is the most serious cause for concern and the reason for requiring a different approach to the evaluation (Horwith and Lindsay, 1997; Bacon, 1993).

Neither economists nor ecologists pretend that they can reasonably quantify all of the direct and indirect benefits that result from healthy functioning wetlands—but most
responsible people in both disciplines acknowledge that these values exist and that there may be a steep price to pay if these ecosystems are destroyed. In areas where mangroves can exist (not all coastline provides the appropriate requirements), they are considered to be the keystone component—essential to the well-being of the nearshore fisheries, seagrass beds and coral reefs (WWF, 1996).

Redonda, and many of the small islands off the Antiguan mainland, especially those in the North Sound, provide valuable nesting habitat for Brown Pelican, Black-crowned Night Heron and several seabird species: Laughing Gull, Roseate Tern, Least Tern, Bridled Tern, Sooty Tern, Brown Noddy, and Red-billed Tropic Bird.

Guiana Island supports a population of between 80-100 West Indian Whistling Ducks. The Society of Caribbean Ornithology considers this species threatened and has established a West Indian Whistling Duck Working Group to collect better regional data on the duck and develop an action plan to safeguard its survival.

Table 1/Appendix 2 below identifies bird species of special conservation concern for the country. This list includes 42 species, or more than 20% of the avian fauna, and is this high because of the extent of threatened habitat in the country.

Note: This list follows the order and nomenclature adopted by the American Ornithologists' Union Check-list of North American Birds (1983, 6th edition), which includes the Caribbean. Other key references (Hunter, U.S. Fish & Wildlife Service, pers comm.; Birdlife International, 1998).
Appendix 3

World Resources Institute's Reefs at Risk Project

Reefs at Risk is a global assessment of likely threats to coral reefs, which will be evaluated under four separate threat factors:

- coastal development,
- marine-based pollution,
- over-exploitation of marine resources, and
- land-based pollution, including sedimentation.

The first three threat factors are evaluated based upon threshold distances from "stressors", while the third involves a more complex watershed-based modeling approach. In the case of coastal development, for example, the stressors potentially threatening reefs include cities, settlements, airports, mines, and tourist resorts.

Some of the associated distance threshold rules are simple, such as, any reef within 10 kilometers of an airport (military or civilian) is under medium threat from that stressor. In the case of cities, the distance threshold is based upon city size and whether or not the given country is likely to have reasonable sewage treatment.

The marine-based pollution threat factor includes as stressors: medium and large-size ports, oil rigs and tanks, and shipping hot spots (zones of high ship traffic and narrow passage).

The over-exploitation threat factor makes use of estimates of coastal population density to estimate the threat from Malthusian over fishing and uses an expert-derived mapping of areas at risk from destructive fishing practices (primarily cyanide and blast fishing).

The original distance thresholds were developed based upon data on known impacted reefs from ICLARM's ReefBase, which were used as distance benchmarks where possible. The set of "stressors" and their associated decision rules were the subject of and were revised as a result of two workshops. The first workshop, where our preliminary results for Africa were presented, was held in Washington DC in early August. Our methodology was revised based upon workshop results and was implemented for the world. The revised methodology and draft global results (as depicted on attached maps) were the subject of a workshop held at ICLARM in Manila in late September. The second workshop led to further refinement of the methodology and the development of two "expert derived" data layers reflecting areas at risk to destructive fishing and "shipping hot spots." (For example, preliminary destructive fishing zones were developed...
based upon 20 km buffers of known occurrences of destructive fishing as shown in ReefBase. These zones were then modified on hardcopy maps at the workshop.)

The Land-based Pollution threat factor is significantly more complicated to implement as it involves hydrologic modeling. A detailed description of the pilot implementation for Africa is available upon request.

Appendix 4

Marine Biodiversity in the Lesser Antilles: The case of Antigua-Barbuda-Redonda

Even though we do not have quantitative data on the deterioration of the Antigua-Barbuda’s marine environment, the trend is clear and disturbing. In 1996, Island Resources Foundation examined a total of 110 sites in 7 areas of the North Sound and found:

- **Most hard corals in shallow areas are dead.** Over 95% of the hard corals surveyed in waters of approximately 9.1 meters or shallower are dead. This problem is spread over a wide geographic area (all seven areas) and occurs in both linear (including bank barrier and fringing reefs) and patch reefs (relatively isolated, with characteristic ring of bare sand from fish and sea urchins that inhabit the reef and graze the vegetation close to it).

- **Deeper reefs tend to be healthier.** Studies confirm this relationship, one recognized by the fishermen and divers. Bunce’s October 1995 post-Hurricane Luis study of several reefs at depths of 9.1-13.7 meters labeled them in “good” health (Bunce, 1996). Other studies of reefs in Antigua and elsewhere in the Caribbean often note the better condition of corals at depths of 18.2 meters and more.

- **Changes in the resource base.** There has been significant deterioration of hard and soft corals with replacement (or overgrowth) of macroalgae and seagrass. Much of the reef recorded in 1988 (Weiss and Multer, 1988) now appears as sand/coral/sea grass.

While it is possible to show that some of the areas previously recorded as coral have deteriorated, the 1988 map does not distinguish live coral from dead coral, and therefore it is not possible to quantify the decrease in the percent of live corals over this time period. However, the few studies that do exist present an alarming picture. Multer collected some live coral coverage data from a few transects in the Great Bird Island area in the 1980s. We resurveyed the approximate areas (but we couldn’t know if we were looking at the exact same spots) and found 75% and more dead coral with isolated live coral heads, where he had recorded less than 25% dead corals (Multer, 1996).

Multer also surveyed reefs in other parts of Antigua (Nonsuch Bay, Goat Head, and Bishops Reef). He first surveyed these sites in 1983, and then resurveyed them in early...
1996. In all three areas, he observed that three-quarters of the corals alive in 1983 were
dead 13 years later (Nonsuch Bay declined from 35% live corals to 7%; Goat Head and
Bishops Reef went from 20% to 5%; and 15% to 2%, respectively). Soft corals showed a
comparable decrease.

Goreau and Goreau (1996) conducted a rapid ecological assessment of coral reefs off the
coasts of Antigua and Barbuda. They also reported that most sites were dominated by
dead coral rubble and had live coral cover of only between 5% and 20%. These figures
were approximately the same as those reached by Bunce (1993; 1996) and the Fisheries
Division, who based their findings on detailed transect surveys.

Equally important in this analysis, is the near-universal response of fishermen and dive
operators, who report the same pattern of deterioration over the past 20 years or more.

Several factors, possibly interacting synergistically, have been proposed to account for
the deterioration of coral reefs in the Caribbean. Although their relative impacts on An­
tigua’s reefs are not known, the following stresses are assumed to be involved:

Natural stresses:
- Predation by other organisms and cannibalism by other corals;
- Crowding and substrate take-over by algae;
- Bleaching;
- Black line disease, white line disease, and related pathogens;
- Physical breakage and high turbidity;
- Long term climate (temperature) changes.

Human-induced stresses:
- Over-fishing;
- Nutrient-enriched runoff and biocides (pesticides, herbicides, and fungicides)
- Hydrocarbons and trace elements from terrestrial waste streams and marine
  products;
- Anchor, boat grounding and swimmer damage and coral removal (site-specific,
  and observed as a factor around Great Bird Island);
- Suspended sediment discharge following rainy periods from unstabilized slopes,
  spoil banks, construction sites, roads, ravines, etc. (world-wide, this is considered
  the greatest single factor).
